The Revenue Algorithm

Redefining the customer journey as a continuous, optimizable system

Consultants and professors have defined the process of generating revenue as a funnel, a bowtie, a linear series of steps, a “Customer Journey,” or a technology stack linked to a series of human tasks. These models are useful for visualization. They are incomplete as operating systems.

An algorithm is a finite, ordered sequence of well-defined, unambiguous steps that takes inputs, performs operations, and produces a specific output. It must be precise enough that a person or machine can follow it without further interpretation, it must eventually terminate, and each step must be executable.

Core properties:

• Finite — it ends after a finite number of steps.

• Definite — every step is clear and unambiguous.

• Effective — each step is basic enough to be performed.

• Input / Output — it accepts inputs and produces outputs.

• Deterministic in the classic sense — the same inputs produce the same outputs, with room for measured branching.

In every case—bowtie, funnel, or journey—the models call out specific steps with defined inputs and outputs leading to a measured revenue outcome: a contract, a renewal, or an expansion. Most include some version of these stages: Awareness or Activation, Education, Selection or Selling, Close or Contract, Onboarding, Adoption, Renewal, and Expansion.

Companies allocate these stages to different leaders and teams. Those teams buy technology, hire staff, and set goals that roll up to a revenue target. The result is a linear system with measurable cycle time. In effect, the company has built an algorithm to create revenue. It is rarely written down. It is almost never optimized. The gaps between stages create perception failures, communication breakdowns, and extended cycle time from first awareness to expansion.

Artificial Intelligence and Leverage

AI will not extend cycle time. It can only shorten it. It works continuously, can execute multiple steps in parallel, and improves the quality of decisions and communications available to the team. The practical question is where that leverage is largest.

The table below shows the estimated revenue impact of a 10 percent improvement in each stage, along with the relative difficulty and cost of achieving it. Revenue impact includes renewals and expansion, not just the initial contract.

Stage	Revenue Impact	Difficulty / Cost
Activation	3%	Low / High
Education	5%	Low / Medium
Selection	10%	High / High
Close	3%	High / High
Onboarding	5%	Low / Low

Stage	Revenue Impact	Difficulty / Cost
Adoption	2%	Medium / Medium
Renewal	10%	Low / Medium
Expansion	5%	Medium / High

Artificial intelligence changes the difficulty and cost column more than any other variable. Tasks that once required significant human time and coordination become feasible to instrument and improve continuously. This is the practical foundation for prioritizing AI investment.

From Discrete Stages to Continuous Accumulation

A revenue algorithm that runs from awareness through expansion can be treated as a continuous process rather than a sequence of discrete stages. Integral calculus supplies the language: instead of maximizing stepwise conversion rates, maximize the accumulated value that results when every contribution across the journey is integrated.

In the conventional bowtie, each stage is optimized separately by improving its conversion rate and cycle time. Under an integral view, the same journey is a continuous path. At every moment t there exists a local intensity of progress, value delivery, and revenue potential. Total realized revenue is the definite integral of that intensity:

R = ∫ from t_awareness to t_expansion of [v(t) · p(t) · r(t)] dt

where:

• v(t) is the instantaneous rate at which value is created or recognized for the customer,

• p(t) is the probability density that the customer remains engaged and progresses,

• r(t) is the revenue capture rate conditional on continued engagement.

The algorithm’s steps become the continuous functions v, p, and r. Optimizing the algorithm means shaping those functions so the integral is maximized, not merely raising a handful of stage-to-stage conversion percentages.

How Optimization Changes

Segment	Conventional lever	Integral lever
Awareness → Education	Lead volume, top-of-funnel conversion	Maximize integral of attention and problem recognition before a formal lead is created
Education → Selection	Content engagement, MQL-to-SQL	Shape the learning curve so the area under the fit-and-trust function rises fastest
Selection → Commit	Win rate, sales cycle length	Integrate instantaneous probability of mutual commitment; reduce time in low-probability states
Commit → Onboard	Time-to-first-value, activation rate	Maximize integral of early value delivery; steeper rise in v(t) enlarges the remaining lifetime integral

Segment	Conventional lever	Integral lever
Onboard → Impact	Adoption metrics, health scores	Treat impact as the running integral of realized outcomes; intervene where the derivative flattens
Impact → Expansion	NRR, upsell rate	Expansion continues the same integral once v(t) exceeds the prior baseline

Because the integral is additive, improvements anywhere on the continuum contribute to the total. A modest increase in the slope of value delivery during onboarding can outweigh a larger percentage-point gain in late-stage win rate, because the former multiplies every subsequent moment of the customer's life.

An Integral Revenue Architecture

The resulting model has several practical consequences:

• Revenue is no longer booked primarily at the Commit knot. It is recognized continuously as the running integral of delivered and captured value.

• Pricing and packaging can be expressed as functions of the same integral (usage, outcome, or impact) rather than fixed stage-gate fees.

• Resource allocation follows the gradient of the integrand. Effort concentrates where the marginal increase in the lifetime integral is largest—often on the right side of the bowtie, where the remaining horizon is longest.

• Customer success, product, and revenue teams share a single objective function—the lifetime integral—rather than separate stage-specific KPIs. The bowtie remains useful as the support of the integral, not as a set of independent funnels.

• Forecasting becomes the evaluation of the expected integral under different interventions.

The revenue algorithm is still the ordered process that begins with awareness and ends with expansion. Integral calculus converts that process from a chain of discrete optimizations into the maximization of a single accumulated quantity. Durable revenue becomes the measured area under the continuous curve of customer value, and every stage of the algorithm is tuned to enlarge that area.
